Abstract

For last two decades different quark models have predicted diverse, sometimes contradictory collections of resonant states. To choose the best among them, the obtained sets had to be compared to available experimental values. In the absence of a more thorough understanding, quark-model resonant states have been directly identified with scattering-matrix singularities. We demonstrate that these are two closely related, but different physical quantities, and offer a model based on the coupled-channel formalism to connect them in an unambiguous way.

I. INTRODUCTION

The missing-resonance problem, a failure to experimentally confirm a number of unambiguously predicted quark-model states (standard, glue enriched, or created from color neutral di- or multi-quark molecules), is for quite some time producing a major queasy in the field of hadron spectroscopy [1]. The dilemma has arisen whether to suspect the soundness of quark model scheme in general, or the very procedure of connecting theoretical predictions with measurable quantities (experimental observables). We track the origin of the problem to the latter. Until today, as no better possibilities have been offered, quark-model resonant states have been directly compared to scattering-matrix pole parameters, disregarding the fact that the equality between the two is valid only if the interaction is neglected; i.e. in the first order perturbation theory. As it has been clearly said in ref. [2], “a calculation of a spectrum should automatically include some description of couplings, as these do affect masses (and vice versa)”. However, instead of doing so, the approach in that reference has been adopted to treat the problem only as an “approximate step-by-step process”, and calculate the first order approximation only. This standing has been followed practically unanimously. Quark-model resonant states are usually compared to Breit-Wigner parameters which serve to quantify experimentally identified scattering matrix resonant-like behavior, entirely forgetting about the dressing effects due to the transition interaction which are necessarily shifting quark-model resonant state values. Furthermore, yet another unresolved issue is for quite some time troubling the physics community: there is a prevailing belief that the Roper resonance differs significantly from other resonances (most recently recapitulated in ref. [3]), but a fully convincing understanding of the phenomenon has never been given. Possible explanations have been ranging from Roper resonance being a hybrid state with excited glue [4], to understanding it as a five quark $qqqq\bar{q}$ state which produces a scattering matrix resonant behavior without a standard three-quark pole term [5] (dynamic resonance).

In this paper we propose a way out for both problems.

Coupled-channel T-matrix formalism (CC_T) [6, 7, 8] by construction distinguishes between scattering-matrix poles and bare Green function (bare propagator) poles. The bare Green function poles, which are the subset of CC_T model fit parameters, can not be detected experimentally. To become observable they have to interact. Through the formalism described by resolvent Bethe-Salpeter equation the self-energy term is generated; the self-energy term shifts the initial real-value bare propagator poles into the complex energy plane; and eventually the measurable complex scattering-matrix poles are generated as dressed Green function poles.

The CC_T formalism we describe, has been known for decades, but until present moment no physical interpretation has been given to bare propagator pole parameters. For the first time, we offer one possibility.

We propose:

the position of a bare Green function pole is to be identified with the mass of a quark-model resonant state (QMRS); the imaginary part of the scattering-matrix pole (SMP), which is created when the interaction effects shift QMRS into the complex energy plane, is to be correlated with its decay width.

Such an identification simultaneously solves both problems: establishes a missing link between QMRS and SMP offering a better control over the missing-resonance problem, and at the same time creates a mechanism how to distinguish between genuine scattering-matrix resonant states (SMRS) and dynamically generated ones. By accepting this assumptions, we are able to: a) identify which QMRS are needed to explain a chosen collection of experimental data; b) determine a nature of a given SMRS (genuine or dynamic).

We believe that the interpretation we propose is a correct one because coupled-channel formalism “simulates reality”. Namely, in the “real world”, bound and resonant states of two or more quarks and antiquarks are considered to be a basis of meson-nucleon interactions. These states, usually described by a quark-model Hamiltonian with its proper values being their bare masses, are not physical observables. To become measurable quantities, these states first have to interact, and only when the interaction is introduced, we can talk about their decay width in its standard physical meaning. The coupled-channel model we use does the same. It starts with bare propagator poles, and through the interaction shifts them into measurable SMPs. So again we end up with two well defined, correlated, but distinguished physical quantities, exactly as we claim the situation in the real world is.

II. FORMALISM

For the convenience of the reader, we shall recapitulate the essence of coupled-channel T-matrix formalism. We use the Carnegie Melon-Berkeley (CMB) approach [6]. CMB model is a separable coupled-channel partial-wave analysis with two main ingredients: bare resonant propagator $G_0(s)$ - the diagonal matrix in *resonant* indices incorporating real first-order poles and the channel-propagator $\Phi(s)$ - the diagonal matrix in *channel* indices with matrix elements $\phi(s)$, which takes care of other non-pole singularities. The solution of the problem, the dressed resonant propagator $G(s)$, is given by the resolvent (Bethe-Salpeter) equation $G^{-1}(s) = G_0^{-1}(s) - \Sigma(s)$, See Fig. 1.a. The self-energy term $\Sigma(s)$, as shown in Fig. 1.b, is built from the channel propagator as $\gamma^T \Phi \gamma$, therefore the model manifestly satisfies unitarity. Both, non-square parameter matrix γ and values of the real bare propagator poles s_0 , are concurrently obtained from the least-square fit of unitary-normalized partial-wave $T = \sqrt{\text{Im}\Phi} \gamma G \gamma^T \sqrt{\text{Im}\Phi}$ to experimental partial-wave data.

The formal way to present the main hypothesis of this article is to discuss the graphical representation of Bethe-Salpeter equation given in Fig. 1.

FIG. 1: Resolvent Bethe-Salpeter equation and self-energy term.

From Fig. 1.a it is clear that measurable SMPs will be given by the poles of the dressed Green function $G(s)$. The resolvent equation states that the dressed propagator poles are generated from the poles of the bare Green function $G_0(s)$ through the process of “dressing” them with the self-energy term $\Sigma(s)$. And this is the term which, as depicted in Fig. 1.b, quantifies the transition interaction when bare propagator poles undergo through all possible intermediate states a_k . Consequently, we end up with two connected sets of poles: bare and dressed Green function poles; different but directly related through the interaction - just like in the “real world”. Therefore it seems natural to connect real-number bare propagator pole s_0 with QMRS; and the imaginary part of the SMP, produced when complex self-energy $\Sigma(s)$ pushes QMRS into the complex energy plane, with the decay width. Let us observe that, in addition to creating the imaginary part, bare propagator poles (QMRS masses) are shifted as well.

By accepting our assumption quite a number of unresolved issues is put into order: SMPs are set apart, but directly linked to the QMRS; the nearest QMRS responsible for a specific SMP can be identified; the mechanism is opened by which the interaction can push the “reasonable” QMRS into the complex energy domain *not accessible* to present experiments (QMRS gets lost); the mechanism is opened by which the SMPs can be created not from QMRS, but otherwise.

III. RESULTS

We illustrate the manner how our hypothesis works on a very simple three channel model.

Even before showing the results, we want to warn the reader that the simplicity of the model, i.e. the fact that we are effectively using only three out of at least seven

accessible and contributing channels, will produce only qualitative results. Complexity of the coupled-channel model (simultaneous mixing of all channels) requires considerable number of parameters, and we expect that the absence of constraining data in more than two channels will necessarily produce instabilities in obtained fitting solutions. We expect to achieve a better quantitative agreement between bare propagator pole position and quark-model results once the stability of the fit solutions is ensured by including other available inelastic channels. What we do need in future, and what we are constantly stressing on numerous occasions (last time in [9]), is to have the constraining data in as many channels as possible. The quality of the data is of importance, but the abundance of constraining channels is what counts.

FIG. 2: The obtained curves for πN elastic channel. Empty squares and red lines denote the real part of the scattering matrix and full squares and blue lines denote the imaginary one.

The first four partial waves in $I=1/2$ channel (S_{11} , P_{11} , P_{13} and D_{13}) were analyzed. We use a model with three channels: two physical two-body channels πN and ηN , while the third, effective channel represents all remaining two- and three-body processes in a form of a two-body process.

For the πN elastic partial waves we used the VPI/GWU single-energy solutions [10, 11].

For the $\pi N \rightarrow \eta N$ partial-wave data we used the coupled-channel amplitudes from Batinić *et al.* [7], but instead of using smooth theoretical curves, we constructed the data points by normally distributing the model input (see ref. [12]).

Fitting strategy was taken over from ref. [12].

FIG. 3: The obtained curves for $\pi N \rightarrow \eta N$ channel.

The obtained curves correctly reproduce all input partial wave data and are given in Figs. 2 and 3 for πN elastic and $\pi N \rightarrow \eta N$ process.

The obtained bare propagator and scattering-matrix poles are collected in Table I.

We show two groups of results: two lowest negative and two lowest positive parity partial waves. The first column contains bare propagator poles produced by the model (upper line, normal text) and one out of several available sets of quark-model masses (lower line, italics) [13]. Second column contains scattering-matrix poles produced by the CC_T model (upper line, normal text) and their standard experimental values (lower line, italics) [14].

First group of results, the two lowest negative parity partial waves S_{11} and D_{13} , pretty well confirms our claims. As can be seen in Table I and in Fig. 4, all three bare propagator poles for both partial waves can be naturally identified with lowest QMRS of refs. [13]. We do see some discrepancies in mass position, but each required bare propagator pole does qualitatively correspond to a particular QMRS, and all lowest QMRS have found their bare propagator counter partners.

The obtained CC_T scattering-matrix pole positions correspond reasonably well to the experimental values reported in ref. [14]. The only disagreement, the unexpected position of the third SMP of the S_{11} partial wave (too far in the complex energy plane), is again a consequence of the fit-results instability, and is expected to disappear with including more channels. All three experimentally detected SMPs for the D_{13} partial wave are reproduced, but the lowest two are somewhat shifted in mass.

The influence of the interaction upon bare propagator poles, and their “journey”

from the initial QMRS to the final SMP positions, is symbolically visualized in Figs. 4 and 5. In the world without interaction γ matrices vanish, we have no “dressing”, and bare propagator and scattering-matrix poles are identical. In the real world, in the world with interaction, the γ matrices are non-vanishing, and are obtained by fitting the partial wave data. Arrows represent the way how bare propagator poles travel from the world without interaction ($\gamma=0$) to the real world scattering-matrix singularities ($\gamma \neq 0$).

FIG. 4: scattering-matrix singularities and bare propagator pole positions for the two lowest negative parity states. Full dots denote bare propagator pole positions, triangle arrows denote the few lowest quark-model resonant state masses of refs. [13].

Next group of results, the two lowest positive parity partial waves P_{13} and P_{11} , is still consistent with the hypothesis of the article, but some problems appear. As can be seen in Table I and in Fig. 5 only one out of five QMRS of ref. [13] for the P_{13} partial wave is identified with the bare propagator pole, while other states

remain yet to be identified. The second required bare propagator pole should either be identified with one of the higher lying QMRS, or will be shifted downwards when results of the fit stabilize.

FIG. 5: scattering-matrix singularities and bare propagator pole positions for the two lowest positive parity states.

The notoriously problematic P_{11} partial wave, however, remains a troublemaker as in majority of theoretical considerations. First, we needed four bare propagator poles in order to achieve acceptable fit to the input data. Having in mind that we should identify bare propagator poles with *all* quark-model states (resonant *and* bound), we have fixed the value of the first bare propagator pole to the mass of the sub-threshold nucleon pole, and left the remaining three poles unconstrained. As shown in Table I, all experimentally determined SMPs [14] are reproduced. So far so good.

Problems start with the identification of QMRS with bare propagator pole position. In ref. [12] we have demonstrated that the presence of inelastic channels directly produces the $N(1710) P_{11}$ SMP, and in Fig. 5 we show that it is generated by dressing the 1.854 GeV bare propagator pole. This pole can be directly associated with one of the quark-model states of ref. [13], either 1.770 or 1.880. The nucleon state is producing an insignificant, sub threshold and experimentally inaccessible pole at 1.1 GeV; remaining two poles at 2.018 and 2.759 produce SMP of 2.2 GeV which can be identified with poorly determined $N(2100) P_{11}$, and an experimentally not yet established state at 2 GeV.

However, our model with constraining data in only two channels shows two very interesting features for P_{11} partial wave: *i) no bare propagator pole which would correspond to the 1.540 quark-model state is needed; ii) one of experimentally confirmed SMPs, namely the $N(1440) P_{11}$ state - Roper resonance, is not produced by any nearby bare propagator pole as it was the case for all other scattering-matrix poles; it is generated differently.*

The CMB model in conjunction with our interpretation of physical meaning of bare propagator poles offers us a natural way to characterize the nature of scattering-matrix resonant state. We propose a criteria: the *genuine* SMRS is a state which is produced by a nearby bare propagator pole; the *dynamic* SMRS is a state which

is created out of distant bare propagator poles through the interaction mechanism itself. Keeping in mind the often expressed belief that the Roper resonance differs significantly from other resonances (recently summarized in [3]), we agree that it might not be a three quark state at all [5]. In our model, Roper resonance turns out to be a *dynamic* scattering-matrix resonant state. The advantage of our model with respect to the approach of ref. [5] is that we do not have to go through a cumbersome procedure of adding an extra pole term to the full K-matrix coupled-channel effective Lagrange model and demonstrate its superfluosnes. Our straightforward criteria: presence or absence of a nearby bare propagator pole gives us immediately the decisive answer. Similarly as in ref. [5], we in our model do find a scattering-matrix pole in the correct energy regime, but that singularity is not produced by a nearby bare propagator pole. In other words, we have no need for such an entity as the “Roper quark-model resonant state”.

IV. CONCLUSIONS

For the first time quark-model resonant states are distinguished from scattering-matrix poles, and are directly identified with a set of fitting parameters (QMRS $\Leftrightarrow$ bare propagator poles of the coupled-channel T-matrix model).

The assumption is tested on a simple three-channel coupled-channel model for the first few partial waves and we show:

The bare propagator poles nicely correspond to the low-lying quark-model resonant states.

The $N(1440)$ P_{11} resonance (Roper resonance) is a scattering-matrix pole *not* produced by a nearby bare propagator pole. Therefore, for the time being, we considered it to be a dynamic resonant state.

The $N(1710)$ P_{11} resonance is a genuine scattering-matrix resonant state produced by a nearby bare propagator pole which can be identified with a quark-model resonant state. However, its final positioning awaits new data in other inelastic channels.

The lowest P_{11} quark-model resonant state of ref. [13] could not be identified when only πN elastic and $\pi N \rightarrow \eta N$ experimental data are used, so we wonder which data and from which process will confirm its existence.
